RayTracer.jl: A Differentiable Renderer that supports Parameter Optimization for Scene Reconstruction

Avik Pal[1]

[1]Indian Institute of Technology Kanpur

ABSTRACT

In this paper, we present RayTracer.jl, a renderer in Julia that is fully differentiable using source-to-source Automatic Differentiation (AD). This means that RayTracer not only renders 2D images from 3D scene parameters, but it can be used to optimize for model parameters that generate a target image in a Differentiable Programming (DP) pipeline. We interface our renderer with the deep learning library Flux for use in combination with neural networks. We demonstrate the use of this differentiable renderer in rendering tasks and in solving inverse graphics problems.

1. Introduction

Rendering is a technique of generating photorealistic or non-photorealistic 2D projections from 3D objects. As such there are several algorithms for rendering complex scenes. One of the most popular techniques for photorealistic rendering is ray tracing. However, for real-time rendering algorithms like rasterization is used.

Ray Tracing is a technique in computer graphics for rendering 3D graphics with complex light interactions. In this technique, rays are traced backward from the eye/camera to the light source(s). The ray can undergo reflection and refraction due to interactions with the objects in its path. This technique, however, is very computationally expensive and hence difficult to do in real-time. But since ray tracing leverages the properties of the materials of the objects in the scene, a natural extension to the rendering problem would be to extract the exact properties of the materials, lighting, etc. given an image of the scene. Unfortunately, ray tracing is non-differentiable at some points and calculating the analytic gradients is a very tedious task. This has made it a very difficult task to present a general inverse rendering method. As such, there is only one framework in our knowledge, redner[8], which has been able to do so by using analytic gradients.

Rendering is a computationally expensive technique, and so it is generally done in static languages like C++. This makes it very time expensive to develop the software. Also, most languages lack the support of the state of the art automatic differentiation tools like Zygote [4], Jax [1], etc which are generally implemented for high-level languages like Julia and Python. As such, it is difficult to develop differentiable renderers in those languages and then interface with popular deep learning software.

In this paper, we explore the idea of differentiability through a renderer, by leveraging the AD in Julia[2]. We present a fully general renderer capable of handling complex scenes and able to differentiate through them. We don't rely on analytic gradients but use source-to-source AD to generate efficient gradient code in the backward pass.

2. Differentiable Ray Tracing

There are several photo-realistic renderers available which contain a vast amount of implicit knowledge. Differentiation allows such renderers to make use of gradients to learn the inverse mapping from an image to its parameter space. We can then use this knowledge in combination with any machine learning / deep learning models to train them in a fast and efficient manner. Experiments in [3] demonstrate the effectiveness of incorporate differentiable renderers in deep learning pipelines by achieving State of the Art results in WIDERFace Hard dataset.

However, as usual, it is difficult to compute efficient derivatives from a production-ready renderer, typically written in a performance language like C++. This provides the primary motivation towards the development of RayTracer.jl. We develop an entire general purpose ray tracer in a high-level numerical computation language. The presence of strong automatic differentiation libraries like Zygote.jl make it trivial to compute efficient derivatives from the renderer. We present the performance gains we get on using Zygote as compared to Central Differencing in Figure 3.

RayTracer.jl [9] is a package for Differentiable Ray Tracing written to solve this particular issue. It relies heavily on the source-to-source automatic differentiation package, Zygote for computing gradients with respect to arbitrary scene parameters. This package allows the user to configure the location of objects, lights and a camera in the scene. This scene is then interpreted by the renderer to generate the image. RayTracer.jl is naturally interfaced with the

deep learning library Flux [5], due to the common AD backend, for use in more complex differentiable pipelines.

3. Scene Rendering

Our approach to differentiable rendering is based on first creating a general purpose renderer and then make use of efficient AD tools for the differentiability part. Hence, at its core RayTracer is a fully featured renderer. It contains functionalities for both raytracing and rasterization. Additionally, unlike most prior work in differentiable rendering we do not make performance compromises in the forward pass (rendering) to allow gradient computation.

RayTracer gives users a lot of control to the user over the scene they want to render. The user controls the lighting in the scene, the shape and materials of the objects and the camera configuration.

3.1 Accelerating the Rendering Process

To accelerate the rendering process we support an acceleration structure, Bounding Volume Hierarchy [6]. We follow the exact same API for ray tracing using these accelerators. In this case instead of passing a *Vector of Objects* we wrap it in a *BoundingVolumeHierarchy* object and pass it. So in order to use this, we would have to change the scene variable to *BoundingVolumeHierarchy(load_obj("teapot.obj"))*.

Using acceleration structures allow us to minimize the total allocations (Figure 1b) and gives us a significant performance boost

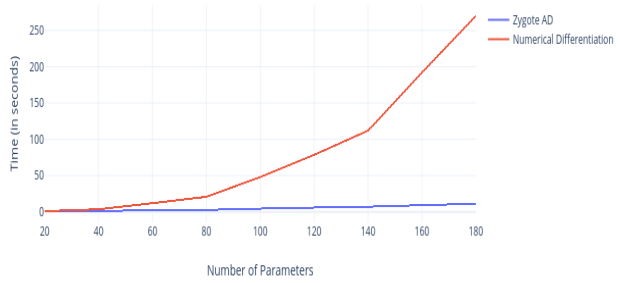

Fig. 3: Performance Comparison between Zygote AD and Numerical Differentiation

(Figure 1a). For these measurements we use a mesh with 137 centered at the origin[1].

3.2 Rendering the Utah Teapot

In this section we demonstrate the general pipeline for defining a 3D scene using RayTracer.jl and then rendering it. We are going to render the popular Utah Teapot model. We need to specify the 3D model in the form of a Vector of Objects. We can do it manually for custom scenes or we could simply load it from a wavefront object (obj) file. Support for additional file formats can be provided via MeshIO.jl. Apart from the scene vector, we need to specify the camera configuration and the configuration of light(s). We summarize the entire code to render the teapot in Listing 1.

```
# Screen Size
screen_size = (w = 512, h = 512)

# Camera Setup
cam = Camera(
    Vec3(1.0f0, 10.0f0, -1.0f0),
    Vec3(0.0f0),
    Vec3(0.0f0, 1.0f0, 0.0f0),
    45.0f0,
    1.0f0,
    screen_size...
)

origin, direction = get_primary_rays(cam)

# Scene
scene = load_obj("teapot.obj")

# Light Position
light = DistantLight(
    Vec3(1.0f0),
    100.0f0,
    Vec3(0.0f0, 1.0f0, 0.0f0)
)

# Render the image
color = raytrace(
    origin,
    direction,
    scene,
    light,
    origin,
    2
)
```

Listing 1: Rendering the Utah Teapot Model

[1] We provide the code for reproducing the experiment in https://github.com/avik-pal/RayTracer.jl/examples

4. Inverse Rendering

The rendering problem is to project 3D scene parameters to form an image in the 2D plane. Inverse Rendering problem is just the opposite: generating a mapping from the 2D image back to the parameters of the 3D scene.

One of the primary motivations of RayTracer.jl is to solve the inverse graphics problem. Since the renderer can be used to compute the gradient with respect to any arbitrary parameter (as long as it is differentiable), we can then use any gradient based optimization technique to optimize on that parameter. This allows us to propose a generalized Algorithm 1 which is capable of optimizing any differentiable parameter.

Algorithm 1: Gradient Based Optimization of Scene Parameters

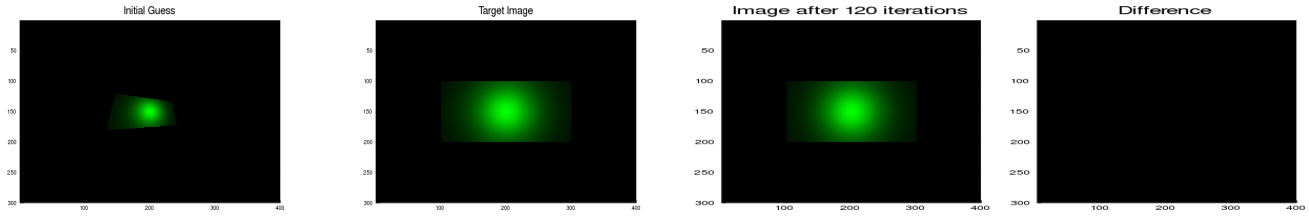
Result: Optimized set of Camera Parameters
Initial Guess of Parameters;
while *not* ***converged*** *or iter* < *max_iter* **do**
    gs = gradient(params) **do**
        img = rendered image with params;
        loss = mean_squared_loss(img, target_img);
    end;
    for *param in params* **do**
        update!(optimizer, param, gs[param]);
    end
    if *loss* < *tolerance* **then**
        converged = True;
    end
end

5. Experiments

In this section we showcase our differentiable renderer in some toy inverse rendering problems. Using the following two experiments we demonstrate the use of gradients obtained via AD to recover the camera, material and lighting parameters for a scene. In both the experiments we make use of the Adam optimizer as described in [7]. We interface the raytracer with Flux to use these optimizers. As an alternative, we have tested the functioning of our package with the optimizers present in Optim.

5.1 Calibration of Camera Parameters

In this experiment we start with the image of a rectangle (Listing 2) under some configuration of the Camera model (Listing 3). Since RayTracer supports only two primitive shapes - Spheres and Triangles, we need to triangulate the rectangle.



(a) Image with uncalibrated camera **(b)** Image to be reconstructed **(c)** Image obtained after optimization

Fig. 4: Calibration of Camera Parameters to reconstruct Image 4b from Image 4a

```
scene = [
    Triangle(
        Vec3( 20.0,  10.0, 0.0),
        Vec3( 20.0, -10.0, 0.0),
        Vec3(-20.0,  10.0, 0.0),
        Material(
            color_diffuse = Vec3(0.0, 1.0, 0.0))),
    Triangle(
        Vec3(-20.0, -10.0, 0.0),
        Vec3( 20.0, -10.0, 0.0),
        Vec3(-20.0,  10.0, 0.0),
        Material(
            color_diffuse = Vec3(0.0, 1.0, 0.0)))
]

light = PointLight(
    Vec3(1.0, 0.0, 0.0),
    100000.0,
    Vec3(0.0, 0.0, -10.0)
)
```

Listing 2: Configuration of the Scene for Experiment 5.1

```
camera_target =
    Camera(
        Vec3(0.0, 0.0, -30.0),
        Vec3(0.0, 0.0,   0.0),
        Vec3(0.0, 1.0,   0.0),
        90.0,
        1.0,
        screen_size...
    )
```

Listing 3: Camera Parameters to be Reconstructed

```
camera_guess =
    Camera(
        Vec3(5.0, -4.0, -20.0),
        Vec3(0.0,  0.0,   0.0),
        Vec3(0.0,  1.0,   0.0),
        90.0,
        3.0,
        screen_size...
    )
```

Listing 4: Initial Guess of the Camera Parameters

Our aim is to reconstruct the image of this rectangle (Figure 4b) by modifying the focus and the location of the camera. We assume that all the other parameters of the model, like the light configuration (Listing 2), position of objects, etc. are known apriori. We use algorithm 1 for optimizing the parameters. We make an initial guess of the parameters and initialize the camera (Listing 4).

As our loss function, we use the mean squared difference between rendered and target images, each with 300×400 pixels having fractional RGB values. We minimize loss with the Adam optimizer, with learning rate 0.05, and declare the model to have converged if loss falls below 10 (where the initial loss is in the order of 600). Figure 4 shows the optimization steps.

5.2 Optimizing the Light Source

In this experiment we describe our solution to the inverse lighting problem. This problem involved predicting the configuration of the light source(s) in the scene given a target image (Figure 5b). All the other information about the geometry and surface properties of the objects and the camera configuration are already known. Listing 5 describes the known configurations.

```
screen_size = (w = 128, h = 128)

camera = Camera(
    Vec3(0.0f0, 6.0f0, -10.0f0),
    Vec3(0.0f0, 2.0f0,  0.0f0),
    Vec3(0.0f0, 1.0f0,  0.0f0),
    45.0f0,
    0.5f0,
    screen_size...
)

scene = load_obj("tree.obj")
```

Listing 5: Configuration of the Scene for Experiment 5.2

The object in our scene is a tree. We start with an arbitrary lighting (Listing 7) condition and then iteratively improve the lighting using Algorithm 1. We present the loss curve and the images generated during the optimization process in Figure 5.

5.3 Retrieving Color of Materials

RayTracer.jl can also be used to recover the properties of the material of a mesh. For this experiment we shall use the same tree mesh from Experiment 5.2. We are going to optimize the diffuse color of the mesh. The position of the camera and the lighting conditions are mentioned in Listing 8.

The major difference of this optimization from the prior experiments is that the range of values the color can take is constrained between 0.0 and 1.0. Hence, after every step of the optimizer we need to clamp the value of the diffuse color for each mesh triangle.

We use the sum squared loss function. We minimize the loss with Adam optimizer, with a learning rate of 0.05. The converge of the model is quite fast and we get a good approximation of the paramters just after a single optimizer step (Figure 6c).

```
screen_size = (w = 400, h = 300)

light = PointLight(
    Vec3(1.0f0),
    1000000.0f0,
    Vec3(0.15f0, 0.5f0, -10.5f0)
)

cam = Camera(
    Vec3(-2.0f0, 2.0f0, -5.0f0),
    Vec3( 0.0f0, 1.7f0,  0.0f0),
    Vec3( 0.0f0, 1.0f0,  0.0f0),
    45.0f0,
    1.0f0,
    screen_size...
)

scene = load_obj("tree.obj")
```

Listing 8: Configuration of the Scene for Experiment 5.3

6. Current Limitations

Despite the success of our approach in solving a variety of inverse graphics problems, we fail to deal with problems that are non-differentiable in nature. One such instance would be estimating the proper geometry of an object given an image. Such problems are non-differentiable due to the large number of discrete choices in the position of the triangle vertices. Hence, trying to optimize such parameters generally causes them to diverge. The other cases which we can't handle properly are secondary lighting (shadows) and global illumination. Most of these cases can be dealt with, similar to the way proposed by [8], but that leads to a significant slowdown to the rendering of the scene.

7. Conclusion

In conclusion, we have showed how Julia can be leveraged to build differentiable systems. We have presented which to the best of our knowledge is the first differentiable renderer which uses source-to-source AD. We have used a set of toy examples to demonstrate the ability of our renderer to reconstruct scenes (which are differentiable) from only a single image. This also shows that this renderer can be used in differentiable programming pipelines which involve image generation.
